## Impossibility of measuring faster-than-c signaling by the Scharnhorst effect

Peter W. Milonni<sup>\*</sup> and Karl Svozil Institute for Theoretical Physics, Technical University Vienna, Karlsplatz 13/136, A–1040 Vienna, Austria.

## Abstract

It is argued that the Scharnhorst effect cannot in principle give rise to measured signal velocities larger than that of light in vacuum.

Scharnhorst [1] and subsequently Barton [2] (see also [3]) have shown that the refractive index of the vacuum between parallel plates can be less than unity for all frequencies  $\omega < mc^2/\hbar$ , where *m* is the electron mass [4]. This arises from the decreased polarizability of the vacuum between the plates *via* virtual electron–positron pair production, suggesting the possibility in principle of faster–than–*c* signal propagation.

Along these lines one could also conceive of a decreased polarizability in the presence of nuclei with charges above the critical charge ( $Z \ge Z_{\rm cr} \approx$ 164–172), associated with the charged vacuum as ground state [5]. In the

vicinity of these nuclei, this would yield a shift of the refractive index given by  $\Delta n(Z) = [1 - \alpha \Pi(Z)]^{1/2} - [1 - \alpha \Pi(Z = 0)]^{1/2} \approx -(\alpha/2) \Delta \Pi \text{ ("dived states")},$ where  $\alpha$  and  $\Pi$  are the fine structure constant and vacuum polarization, respectively, yielding a contribution to  $\Delta n \approx \Delta c/c = -\mathcal{O}(\alpha)$  which is one order in the fine structure constant *lower* than the Scharnhorst effect.

The decrease of n can be related to the negative expectation value of the electromagnetic energy density u between the plates via the effective potential method. In terms of the effective potential  $\Gamma(A_{\mu})$  ( $A_{\mu}$  stands for the expectation value of the electromagnetic field) and for vanishing momenta, u may be written as [6]  $\Gamma(A_{\mu}) = -(2\pi)^4 \delta(0) u(A_{\mu})$ . It can be shown that u is given by the sum containing all one-particle irreducible (1PI) Green's functions with vanishing external momenta:  $u(A_{\mu}) = -\sum_{n=2}^{\infty} (1/n!) \tilde{\Gamma}^{(n)}(0, \ldots, 0) A_{\mu_1} \ldots A_{\mu_n}$ . The one-loop four-point Green's function has been used by Scharnhorst to calculate the photon polarizability via electron-positron pair production. (Of course, this does not rule out cancellations of terms  $\tilde{\Gamma}^{(n)}A_{\mu_1} \ldots A_{\mu_n}$  within the summation.)

The fact that u < 0 is associated with an attractive force between the plates (Casimir effect), and has already been invoked in the somewhat similar context of wormholes and time machines [7]. The Scharnhorst effect is much too small to imagine experimental tests, but it nevertheless raises an important point of principle about whether it is possible for signal velocities to exceed the velocity c of light in vacuum. [1, 2, 3] In this letter we show that the Scharnhorst effect does not in principle allow one to measure signal

velocities v > c.

A direct measurement of v would involve a measurement of the time trequired for propagation over a fixed distance L': v = L'/t. Due to any uncertainty  $\Delta t$  in the measured time, the value of v deduced in this way is uncertain by the amount  $\Delta v = L'\Delta t/t^2 = c^2\Delta t/L'$ . For the present discussion we take L' = L, the plate separation in the Casimir vacuum considered by Scharnhorst and Barton; this *minimizes* the uncertainty in the measured velocity. [8]

The uncertainty  $\Delta t$  will be limited, aside from practical considerations, by the uncertainty in time it takes to switch on a signal. For instance, if a photon emitter is switched "on" at time t = 0, by exciting an atom, there is a fundamental uncertainty as to when the quantum jump and photon emission will occur. In the most optimistic case imaginable  $\Delta t = 1/\omega$ , where  $\omega$  is the frequency of the signal. We could also choose  $\Delta t$  to be the radiative lifetime of an atom, but this would lead to a larger value of  $\Delta v$ , and for the present argument we wish to examine the situation most favorable to the possibility of faster-than-c signaling. Thus we take  $\Delta v = c^2/\omega L = c\lambda/L$ , where  $\lambda$  is the wavelength of the signal radiation.

The change in c predicted by the Scharnhorst effect is  $\Delta c = \kappa \alpha^2 \hbar^4 / m^4 c^3 L^4$ , where  $\alpha$  is the fine structure constant ( $\cong 1/137$ ) and  $\kappa \cong 1.3 \times 10^{-2}$  [2]. Thus the ratio of the uncertainty in a measured value of v to  $\Delta c$  is

$$\frac{\Delta v}{\Delta c} = \frac{1}{\kappa \alpha^2} \left(\frac{\lambda}{L}\right) \left(\frac{mcL}{\hbar}\right)^4 = \frac{1}{\kappa \alpha^2} \left(\frac{\lambda}{\lambda_c}\right) \left(\frac{L}{\lambda_c}\right)^3 \quad , \tag{1}$$

where  $\lambda_c = \hbar/mc$  ( $\cong 3.9 \times 10^{-11}$  cm) is the electron Compton wavelength.

Barton has noted that the assumption  $\lambda/L \ll 1$  is required not only in order to permit clean thought experiments, but also to justify the assumption of a local refractive index. The theory also assumes  $\lambda \gg \lambda_c$ ; in order again to be as optimistic as possible in our analysis of the Scharnhorst effect, and to minimize  $\Delta v$ , we use  $\lambda = \lambda_c$  in (1):

$$\frac{\Delta v}{\Delta c} \ge \frac{1}{\kappa \alpha^2} \left(\frac{L}{\lambda_c}\right)^3 \approx 1.5 \times 10^6 \left(\frac{L}{\lambda_c}\right)^3 \quad . \tag{2}$$

Morris *et al.*, in their discussion of wormholes and time machines [7], have noted that plate separations less than the Compton wavelength "might well be forbidden". In this connection note that, if  $L = \lambda_c$ , then  $t = \hbar/mc^2 \equiv$  $1/\omega_{\text{max}} < 1/\omega = \Delta t$ . (Recall that the Scharnhorst theory assumes  $\omega < \omega_{\text{max}}$ .) In other words, if  $L = \hbar/mc$  the uncertainty in the time it takes a signal to traverse the distance L is larger than t = L/c. This would imply  $\Delta v > c$ . A more reasonable lower limit on L might be the Bohr radius  $a_0 = \lambda_c/\alpha$ , in which case

$$\frac{\Delta v}{\Delta c} \approx \frac{1}{\kappa \alpha^5} \approx 3.7 \times 10^{12} \quad . \tag{3}$$

At such tiny separations the distinction between the plates as macroscopic objects becomes blurred, of course, and repulsive forces associated with overlapping electron wavefunctions come into play to increase u and weaken and remove the Scharnhorst effect. In any case it is clear that the uncertainty in the measured propagation velocity will always be enormously larger than the correction to c associated with the Scharnhorst effect.

We conclude, therefore, that no measurement of the faster-than-c velocity

of light predicted by the Scharnhorst effect is possible. It is worth noting that our conclusion assumes the small value of the fine structure constant determined by  $e, \hbar$  and c. In a universe in which  $\alpha$  were large, our conclusion would not hold. In other words, our conclusion rests on the small value of the fine structure constant rather than the basic dynamical laws of physics. This is not the first example where a violation of causality is ruled out by the values of constants rather than dynamical laws [9].
